Abstract

Rule based reasoning (RBR) and case based reasoning (CBR) have emerged as two important and complementary reasoning methodologies in artificial intelligence (AI). For problem solving in complex, real world situations, it is useful to integrate RBR and CBR. This paper presents an approach to achieve a compact and seamless integration of RBR and CBR within the base architecture of rules. It is shown that the integration of CBR and RBR is possible without altering the inference engine of RBR. The paper focuses on the possibilistic nature of the approximate reasoning methodology common to both CBR and RBR. In CBR, the concept of similarity is cast as the complement of the distance between cases. In RBR the transitivity of similarity is the basis for the approximate deductions based on the generalized *modus ponens*. This integration is illustrated in the financial domain of mergers and acquisitions. These ideas have been implemented in a prototype system, called MARS.

Keywords: *Case-based reasoning, Rule-based reasoning, Plausible reasoning, Possibility Theory, Financial application of Knowledge Based Systems*

1 Introduction

In this section, we introduce rule based and case based reasoning methodologies, describe some important related issues, emphasize the need for their integration and outline the focus and structure of the paper.

1.1 Rule Based and Case Based Reasoning

Rule based reasoning (RBR) [BS84] is one of the most popular reasoning paradigms used in artificial intelligence (AI). The reasoning architecture of rule based systems has two major components: the *knowledge base* (usually consisting of a set of “IF...THEN...” rules representing domain knowledge) and the *inference engine* (usually containing some domain

independent inference mechanisms, such as *forward/backward chaining*). The general solution of RBR is shown in Figure 1. Given an input problem, applicable rules are first found by matching against the rules in the knowledge base; then, intermediate results are generated by the chosen inference mechanism (such as forward or backward chaining) and the process is repeated till the desired solution state is reached. The chosen inference mechanism (forward/backward) determines whether the *antecedents* (forward) or the *consequents* (backward) of the rules in the knowledge base are used for matching and whether the desired solution state is the attainment of a particular conclusion (forward) or the determination of the existence of certain data (backward). The knowledge base contains the domain knowledge pertinent to the problem, and the solution is, in general, found by incrementally exploring the rule graph formed by the rules in the knowledge base.

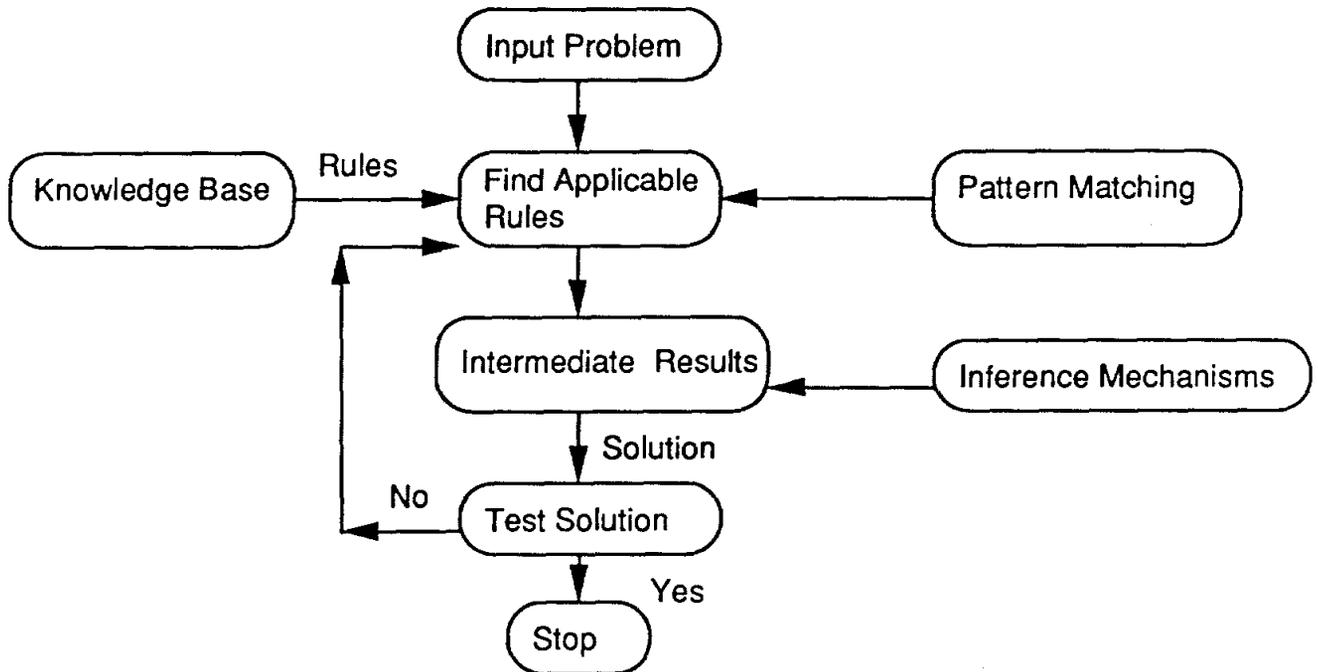

Figure 1: Solution Structure in RBR

Case based reasoning (or analogical reasoning), though common and extremely important in human cognition, has only recently emerged as a major reasoning methodology. Case based reasoning (CBR) involves solving new problems by identifying and adapting *similar* problems stored in a library of past experiences/problems. The reasoning architecture of CBR consists of a *case library* (stored representations of previous experiences/problems solved) and an *inference cycle*. The important steps in the inference cycle of CBR are to *find* and *retrieve* cases from the case library which are most relevant to the problem at hand (input) and to *adapt* the retrieved cases to the current input. This has been illustrated in Figure 2. Within this broad framework, two major classes of CBR can be identified [RS89b]: *problem solving CBR* and *precedent based CBR*. In problem solving CBR, the emphasis is on adapting the retrieved cases to find a plan or a course of action to solve the input problem (such as in

industrial design and planning [BM88]). In contrast, the focus in precedent based CBR is to use the retrieved cases to justify/explain an action/solution (common in legal reasoning [AR88]).

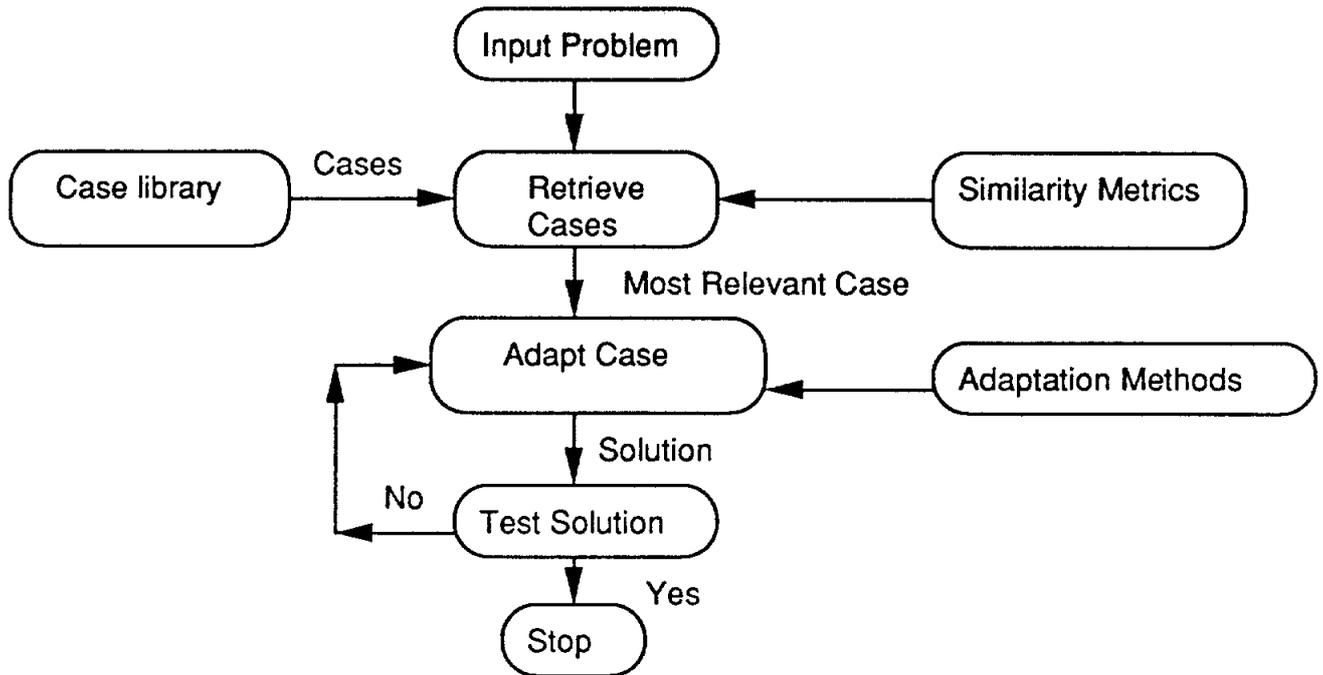

Figure 2: Solution Structure in CBR

Comparison of Figures 1 and 2 provides an useful perspective on RBR and CBR. The general solution structures of both RBR and CBR are quite similar: in both some matching (against either rules or cases) is performed and then some procedures (inference mechanisms or adaptation techniques) are used iteratively to generate the desired solution. This hints to the fact that it may be possible to seamlessly integrate RBR and CBR. However, there are some important differences between RBR and CBR, as typically discussed in the literature. Cases in the case library are, in general, more complex structures than simple IF..THEN.. rules and a variety of representational schemes (such as frames and MOPS [RS89a]) have been used in the literature to represent their complexity. Pattern matching in CBR is usually more involved than simply matching the LHS (*antecedents*) or the RHS (*consequents*) of rules (in RBR). This complexity is caused by the data structures used to represent the case library and the fact that the match of the input problem with the various cases in the case library is usually partial. Unlike RBR, where a solution is obtained by incrementally searching the rule graph, CBR typically generates a complete solution (the selected case from the case library) first, and then progressively adapts it to solve the problem at hand. While there are well defined procedures (such as backward or forward chaining) for searching a rule graph, there are no equally well defined procedures for case adaptation as it is usually ill-structured and thus less susceptible to generalization.

1.2 Issues in RBR and CBR

From Figures 1 and 2 and the above description, one can identify several important issues in RBR and CBR. We outline below some of these issues which are most relevant to this paper and explain our treatment of them in later sections (sections 4.2 and 4.3).

1.2.1 Rule Based Reasoning

Issues of concern in RBR are:

- **Nature of Facts & Rules:** In conventional RBR, facts and (IF..THEN..) rules are strictly *categorical* in nature (e.g., IF *it is cloudy* THEN *it shall rain*). Both commonsense knowledge and domain expertise are more naturally expressed in terms of plausible rules (e.g., IF *it is cloudy* THEN *it is POSSIBLE that it may rain*). Conventional IF..THEN.. rules also require a strict Boolean match on the *premises* and the *conclusions*. However, this is very restrictive as real world situations are often fuzzy and do not match exactly with rule premises and conclusions. For example, the premise *it is cloudy* is fuzzy and many a time the sky can be classified as *partially cloudy*. Thus, it is necessary to be able to accommodate partial degrees of belief in rule premises and conclusions.
- **Inference in Rule Graph:** Given the above stated need to incorporate uncertainty in the structure of rules, some mechanisms have to be used to propagate the partial degrees of belief through the rule graph to determine the degrees of confirmation and refutation of the various conclusions. These mechanisms include means to aggregate the uncertainty of the premises, propagate this uncertainty to the conclusions and aggregate the uncertainty of the conclusion. The last task is important because a particular conclusion may be reached via multiple proof paths, each path contributing to the confirmation or refutation of the conclusion. Different uncertainty calculi are described in the literature to deal with some or all of these aspects.
- **Structure of Knowledge Base:** Large knowledge bases can contain many (hundreds or thousands of) rules, and under such conditions, it is necessary to structure the knowledge base appropriately for the purposes of efficiency in inference and ease of debugging and knowledge engineering. *Partitions*, *abstraction hierarchies* and *contexts* are some of the techniques used in the literature for structuring the knowledge base. *Belief revision* mechanisms are also required for maintaining the validity and consistency of the knowledge base.

1.2.2 Case Based Reasoning

Important issues in CBR are:

- **Representation:** This refers to the representational scheme used for the cases in the case library. There are several dimensions along which this issue can be analyzed. The data or memory structure for cases popular in the literature are frames or some variant of a frame system, such as MOPS [RS89a]. Cases can also be stored in an

interpreted or *uninterpreted* format. In an interpreted format, all relevant features and event sequences are explicitly stored; while in an uninterpreted format, some features and events have to be derived later. The description of cases in the case library can also be *complete* or *partial*.

- **Structure of Case Library:** In practice, the number of cases in a case library can be vary large. It is important to be able to efficiently index and search through the case library to retrieve the most relevant case. A variety of techniques are used in the literature, including *flat structures* (with serial or parallel searches) and many variants (*shared feature/prioritized/redundant* [RS89a]) of discrimination nets. The selection of surface features and indices play an important role here.
- **Need:** Case base reasoning is useful only for solving certain kinds of problems (e.g., legal reasoning) and under certain conditions (e.g., when domain rules are expensive and hard to formulate). It is important to be able to identify this need for CBR and then either activate or deactivate CBR in a problem solver.
- **Retrieval & Similarity Metrics:** While determining which case to retrieve from the case library, it is important to get not just the most *similar* case, but the most *relevant* case. Simple *static* evaluation metrics (such as predetermined weights) can often lead to surprising results. More sophisticated *dynamic* metrics which take into account factors such as prior experiences, anomalies [Sch90], expectations and the particular goal/task under consideration generally yield better results. The description of uncertainty and imprecision (given above for rule premises in RBR) is also true here. Matches between the input problem and the cases are usually partial.
- **Adaptation:** This is perhaps the least structured and most difficult part of the CBR solution. There are few general guidelines. Adaptation methods can be classified into two broad categories: *structural*, i.e., directly modify the solution from the retrieved case and *derivational*, i.e., re-run the solution procedure of the retrieved case. Specific procedures used in the literature include *parameter manipulation*, *critic based adaptation* and *reinstantiation* [RS89a].
- **Integration:** Much of the current research in CBR considers it in isolation from other reasoning techniques. However, in general, CBR is just another proof (solution) path to a goal (problem). It is important to consider the interactions of CBR with other reasoning methodologies that might also be employed in a problem solver.

While the issues of *representation*, *structure*, *retrieval*, *similarity metrics* and *adaptation* have been discussed in the literature, the issues of *need* and *integration* have received comparatively negligible attention. This is because most prior research in CBR has considered CBR in isolation and has ignored its interaction with other reasoning methodologies. It is only recently that some researchers [RS89b] [Goe90] [BW90] have begun exploring the interactions of CBR with other reasoning methodologies. Figure 3 conceptually illustrates how CBR would be integrated into a reasoning system which might employ other reasoning methodologies (such as RBR and/or model based reasoning) besides CBR. Note that there is now a need for *aggregating* the solutions obtained via CBR and other reasoning techniques.

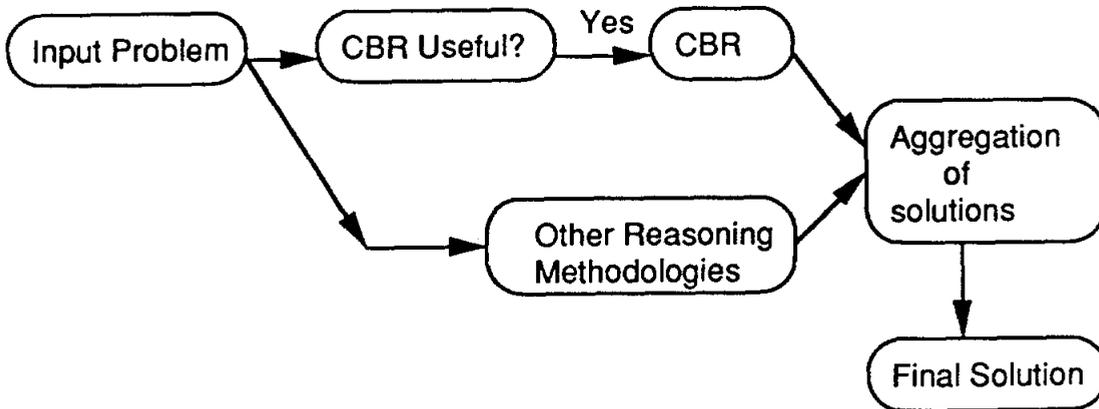

Figure 3: Integrating CBR with Other Reasoning Methodologies

1.3 Uncertainty in RBR and CBR

It is evident from the above description that uncertainty is pervasive in the reasoning cycle of deductive (rule-based) and analogical (case-based) reasoning systems.

In Rule-Based Reasoning (RBR), uncertainty is present both in the domain knowledge (*plausible rules* and *fuzzy/imprecise* premises) and in the inference techniques used to search the rule graph.

In CBR, uncertainty is present in the semantics of *abstract features* used to index the cases, in the evaluation and (hierarchical) aggregation of the *similarity measures* computed across these features, in the determination of *relevancy and saliency* of the similar cases, and in the solution adaptation phase.

In Section 2.2 we will show how most of this uncertainty can be modeled by using fuzzy predicates and plausible rules to derive abstract features from the surface features. Similarity measures can be defined as the complement of metrics between fuzzy-sets (cases). The similarity measure can be aggregated or chained (using the transitivity of similarity) according to well-defined operators (Triangular norms.)

1.4 Integration of Reasoning Methodologies

The need to integrate diverse reasoning techniques for effectively solving complex real world problems has been recently recognized by the AI community. This is represented in the works of Carbonell and Veloso [CV88] (integration of CBR and classical search problem solvers), Hammond and Hurwitz [HH88] (integrating CBR and explanation based reasoning), Rissland and Skalak [RS89b] (integrating RBR and CBR), Goel [Goe90] (integrating CBR and model based reasoning) and Braverman [BW90] (integrating CBR and explanation based learning).

RBR and CBR are largely *complementary* reasoning methodologies. RBR can better represent specialized domain knowledge in a modular, declarative fashion, while CBR can better represent past experiences and domain complexity [RS89a]. Significant benefits are possible by combining RBR and CBR. For example, CBR can directly enhance RBR by providing a context for screening the knowledge base and by extending the coverage of rules

by representing exceptions (to the rule) in the form of cases. Going the other direction, RBR can enhance CBR by expressing domain knowledge to dynamically determine the contextually dependent relevance of a feature set (or attributes of a case) to a given goal and to dynamically select the best similarity/relevancy measure to use for case retrieval. There are numerous domains in which it is important to combine RBR and CBR, e.g., the legal domain (see Section 3.3 for an example).

1.5 Focus and Structure of Paper

This paper is concerned with the integration of RBR and CBR in an uncertain and dynamic world. Rather than “patching together” two different types of representational and reasoning frameworks, we have chosen to attempt the integration within one architectural framework, namely that of RBR. RBR has been chosen as the base architecture as it is still the most popular and commercially successful AI reasoning methodology. As shown in later sections, it is possible to achieve a compact, seamless integration of the two reasoning methodologies without changing the inference engine of RBR. This has, as discussed later, some advantages over other architectures (e.g., the one of Rissland and Skalak [RS89b]). The incorporation of uncertainty into the reasoning framework gives the system added power in handling real world situations, which are almost invariably uncertain and dynamic. It also leads to a more accurate treatment of CBR, as it is inherently a non-deductive form of approximate reasoning in which there is significant uncertainty and imprecision, e.g., in the semantics of the case features and in determining the similarity/relevancy of prior cases to the input problem/goal. The significance of our work arises from the fact that though RBR and CBR are two extremely important reasoning methodologies, there has been very little research in combining the two.

The domain chosen for the illustration of our ideas is the financial domain of mergers and acquisitions (M&A). M&A represent a real world situation, which is complex, uncertain, dynamic and relevant for business today. The ideas and technical approach detailed in this paper have been implemented in a prototype system, called MARS [BD90].

This paper contains four other sections. Section 2 illustrates the role of approximate reasoning techniques and contrasts probabilistic and possibilistic reasoning systems. A brief introduction to the domain of M&A is provided in Section 3. The need for integrating RBR and CBR in this domain is also explained in that section. Section 4 provides an overview of MARS, illustrates the nature of possibilistic reasoning in MARS, and then describes the integration of RBR and CBR in MARS. Section 5 compares our work with related research and concludes the paper by describing the contributions and limitations of this research.

2 Approximate Reasoning Systems

The task of a reasoning system is to determine the *truth value* of statements describing the state or the behavior of a real world system. However, this hypothesis evaluation requires complete and certain information, which is typically not available. Therefore, approximate reasoning techniques are used to determine a *set of possible worlds* that are logically consistent with the available information. These possible worlds are characterized by a set of

propositional variables and their associated values. As it is generally impractical to describe these possible worlds to an acceptable level of detail, approximate reasoning techniques seek to determine some properties of the set of possible solutions or some constraints on the values of such properties [Rus90b].¹

A large number of approximate reasoning techniques have been developed over the past decade to provide these solutions. (See references [Bon87a], [Pea88] for a survey). These techniques can be roughly subdivided into two basic categories according to their *quantitative* or *qualitative* characterizations of uncertainty. Among the quantitative approaches, we find two types of reasoning that differ in the semantics of their numerical representation. One is the *probabilistic reasoning* approach, based on probability theory. The other one is the *possibilistic reasoning* approach, based on the semantics of many-valued logics. We will briefly contrast these two types of quantitative representations and focus our discussion on possibilistic reasoning systems.

2.1 Probabilistic and Possibilistic Reasoning Systems

Probability-based reasoning, or *probabilistic reasoning* seeks to describe the constraints on the variables that characterize the possible worlds with conditional probability distributions based on the evidence in hand. Their supporting formalisms are based on the concept of *set-measures*, additive real functions defined over certain subsets of some space.

These methods focus on chance of occurrence and relative likelihood. They are oriented primarily toward the choice of decisions that are optimal in the *long-run*, as they measure the *tendency* or *propensity* of truth of a proposition without assuring its actual validity. Thus, probabilistic reasoning estimates the frequency of the truth of a hypothesis as determined by prior observation (objectivist interpretation) or a degree of gamble based on the actual truth of the hypothesis (subjectivist interpretation).

Possibilistic reasoning, which is rooted in fuzzy set theory [Zad65] and many-valued logics, seeks to describe the constraints on the possible worlds in terms of their *similarity* to other sets of possible worlds.

These methods focus on *single* situations and cases. Rather than measuring the tendency of the given proposition to be valid, they seek to find another proposition that resembles (according to some measure of similarity) the hypothesis of interest but that is valid. Thus, possibilistic reasoning asserts that a related, similar (and usually less specific) hypothesis is true.

2.2 Possibilistic Reasoning

Given the purpose and characteristics of probabilistic and possibilistic reasoning, it is clear that these technologies ought to be regarded as being complementary rather than competitive.

The single-case orientation of possibilistic techniques makes them particularly suitable for case-based reasoning. In CBR, it is typically the case that the problem in hand (probe)

¹The authors want to acknowledge Enrique Ruspini's private communication, which is the basis for the content of this section. The interested reader should consult reference [Rus87], [Rus89], [Rus90b] for a further elaboration of this topic.

has never been encountered before. The inference in CBR is based on the existence of cases *similar enough* (i.e. close enough) to the probe to justify the adaptability of their solution to the current problem.

The notion of similarity is based on the concept of *metric* or distance, as opposed to that of set measure. Distances are functions which assign a number greater than zero to pairs of elements of some set (for sake of **simplicity**, we will assume the range of this function to be the interval $[0,1]$). Distances are *reflexive*, *commutative*, and *transitive*. Similarity can be defined as the complement of distance, i.e.:

$$S(A, B) = 1 - d(A, B)$$

The basic structural characteristics of the similarity functions is an extended notion of transitivity that allows the computation of bounds on the similarity between two objects A and B on the basis of knowledge of their similarities to a third object C:

$$S(A, B) \geq T(S(A, C), S(B, C)),$$

where T is a Triangular-norm [BD86], [Bon87b]. Any continuous triangular norm $T(A, B)$ falls in the interval $Max(0, A + B - 1) \leq T(A, B) \leq Min(A, B)$. Thus, we can observe that if we use the lower bound of the range of T-norms in the expression describing the transitivity of similarity, we obtain the triangular inequality for distances. If we use the upper bound, we obtain the ultrametric inequality.

This similarity notion is a direct extension of the notion of *accessibility relation* that is of fundamental importance in modal logics. This notion is further described by Ruspini in these proceedings [Rus90a]. In summarizing Ruspini's results, we can observe that the notion of accessibility captures the idea that whatever is true in some world w , is true, but in a modified sense, in another w' that is accessible from it. When considering multiple levels of accessibility (indexed by a number between 0 and 1), this relation, measuring the resemblance between two worlds, may be used to express the extent by which considerations applicable in one world may be extended to another world.

The basic inferential mechanism, underlying the *generalized modus-ponens* [Zad79], makes use of inferential chains and the properties of a similarity function to relate the state of affairs in the two worlds that are at the extremes of an inferential chain.

We have briefly summarized the semantics of possibilistic reasoning, its role in determining the similarity between possible worlds (cases), and its mechanism to propagate similarities through a reasoning chain (rule chain). On this basis, we have established a common ground upon which we can build the integration of CBR and RBR. Before proceeding to describe such an integration, we need to justify the reasons for integrating these two methodologies. This motivation will be provided by the description of the problem domain of Mergers and Acquisition (M&A), which is used to test the integration.

3 Mergers & Acquisitions (M&A)

This section introduces the domain of M&A and emphasizes the need for integrating RBR and CBR in M&A.

3.1 Introduction and Overview

The structure of corporate USA has been changed dramatically by the flood of mergers and acquisitions witnessed over the past years. Today, a flurry of mergers are sweeping through European industry as it prepares for 1992. Annually, these deals total tens of billions of US dollars. The average M&A deal is enormously complex and involves sophisticated reasoning and planning on the part of several parties. To lend some useful conceptual abstraction, we can consider two players of interest in simple M&A deals: the *raider* (who usually initiates a take-over attempt) and *the target* (which is the company of interest to the raider). Another player of interest who is outside the structure of the actual M&A deal, but has a keen interest in the entire process is the *professional arbitrageur* (who tries to make arbitrage profit by wisely shifting his investments during the merger process).

While the actions of each of these players vary from deal to deal, it is possible to identify certain basic actions associated with their individual roles. For example, some of the representative actions of a raider are:

- **Target Monitoring:** The raider has to track possible takeover targets by constantly evaluating different aspects of the various companies in accordance with his own goals, which could be *benevolent* (acquire, integrate and manage the target company) or *malign* (bust the target for quick profits).
- **Target Evaluation & Selection:** The raider has to select a particular company as the target. This is usually done with extreme care as the entire process of a M&A deal is very risky and expensive, both in time and money.
- **Merger Strategy Selection:** The raider has to select the desired strategy of attack once a target has been selected. This involves complex reasoning and planning and is dependent on the raider's perception of the reaction of the management and stockholders of the target company.
- **Target Response Evaluation & Attack Strategy Modification:** The target's response (*acceptance* or *defiance*) to the raider's merger offer determines how the raider subsequently modifies the chosen attack strategy.

Even in simple M&A deals, other complicating factors, such as multiple bidders and legal complications, often arise. The reader may consult the references [Fer87], [Mic86], [Roc87] for more details on various aspects of M&A.

3.2 RBR and CBR in Mergers & Acquisitions

The above section provided a glimpse of the complex reasoning and planning required on the part of the various players in a M&A deal. Though a variety of reasoning & problem solving methodologies are required for every step in the M&A deal (see reference [DB90] for details), RBR and CBR play a crucial role in the process.

RBR can be used to represent the domain expertise that is required for structuring various aspects of the M&A deal or deciding upon the next best course of action. For example the

raider may have certain expertise (rules) to determine which company to select as a possible target (this is similar to a classical *diagnostic* problem).

CBR also plays an extremely important role in the M&A process. For example, the prior experiences of other companies subject to hostile takeovers often guide the targets evaluation of and response to a hostile takeover bid by the raider. Even a cursory glance over a professional guide to mergers and acquisitions (e.g., see reference [Kuh90]) reveals the extensive use of prior cases for justifying strategies or explaining certain actions. Within the entire range of activities in a M&A deal, CBR is perhaps most useful for the legal and tax related aspects. We explain below in some detail how both RBR and CBR are required for reasoning about one aspect of a M&A deal: the *anti-trust* defense.

3.3 The Anti-trust Defense

Usually, when a raider launches a hostile takeover attempt, the target has to devise an elaborate defense strategy. Michel and Shaked [Mic86] note that “*anti-trust arguments are one of the most frequently used forms of merger defense*”. The laws governing anti-trust cases depend on several merger guide-lines (e.g., the 1982 and 1984 guide-lines) issued by the Department of Justice (DOJ) (in the USA). Much of the reasoning involved in the interpretation and application of guide-lines regarding anti-trust laws can be expressed by rules. For example, the 1982 guide-lines specified that markets where the post merger HHI (a mathematical measure of market concentration) was above 1800 were *highly concentrated* and if the post merger HHI was between 1000 and 1800, then the market was *moderately concentrated* and so on. However, such rules by themselves are not enough as [Mic86] “*it is not possible to remove the exercise of judgement from the evaluation of mergers under the anti-trust laws*”. This exercise of judgement is predominant in resolving issues like definition and measurement of market, efficiency arguments and treatment of foreign competition. This is where CBR can help and is used extensively.

For example, consider the \$5.1 billion attempt by Mobil to takeover Marathon on Nov. 1, 1981. Marathon began the takeover defense by filing an anti-trust lawsuit against Mobil (if successful, Mobil would then become the largest marketer of gasoline in the USA with an estimated 10% market share). The key issue here was whether section 7 of the Clayton Act (which provides that “*no person .. shall acquire .. stock .. where, in any line of commerce .. in any section of the country, the effect of such acquisition may be substantially to lessen competition*”) was being violated by the merger. Judge J. M. Manos of the Ohio Court ruled against Mobil and in his ruling [Mic86] “*referred to past cases similar to the Mobil-Marathon situation. In the 1962 case of Brown Shoe Company, the combined market share of Brown Shoe and G.R. Kinney Co. was found to exceed 5% nationwide, rising to 57% in some cities. In the 1966 case of Pabst Brewing Company, the merged firm would have had a combined market share of 4.49% in the USA and up to 23.95% in Wisconsin.*” In all these three cases, section 7 of the Clayton Act was found to be violated.

This brief example illustrates the important role that cases and rules have in the M&A domain and stresses the need for their integration.

3.4 Computer Tools For M&A

Personal contacts and human communication perhaps play the the most important role in determining the outcome of a M&A deal. However, a variety of computer tools are also available commercially for assisting decisions regarding various aspects of a M&A deal. These tools use quantitative (financial) **data and conventional** statistical models to generate historical and forecasted financial statements, balance sheets, financial ratios, accounting combinations and other similar results. Typically these tools do not provide support for other useful features such as intelligent information retrieval (from on-line news services), RBR (expert knowledge), CBR, uncertainty management and dynamic planning (see [BD90]). Below we introduce MARS, our prototype system which attempts to provide support for such facilities in an integrated environment.

4 MARS: A Mergers & Acquisitions Reasoning System

In this section, we first provide a quick overview of MARS and then focus on the integration of RBR and CBR within MARS.

4.1 Overview of MARS

MARS [BD90] is a prototype AI reasoning system that both simulates and provides expert advice regarding the actions of the raider, the target and the arbitrageur. The general software architecture of MARS is as shown in Figure 4. There are four independent simulators. The global simulator provides a simulation of the variations of the macro-economic variables affecting the M&A deal (e.g., the interest rate and the T-Bill price). The three other simulators simulate the reasoning and planning strategies of the raider, target and the arbitrageur respectively. There is a fusion of different reasoning techniques in all four simulators and each of them is independently capable of integrated reasoning and planning with uncertain, incomplete and time varying information.

MARS is implemented in Common LISP using KEE and Reasoning with Uncertainty Module (RUM) [BGD87], and runs on the Symbolics. The knowledge base of MARS is frame based and consists of approximately 550 KEE units. Figure 5 shows the user interface for MARS. More details on the structure, implementation and use of MARS can be found in [BD90].

4.2 RBR in MARS

MARS is implemented using RUM [BGD87] and KEE. Though RUM uses the data structures and graphical interface of KEE, it has its own rule system. We describe below how some of the important issues in RBR (mentioned in section 1.2.1) are addressed in MARS:

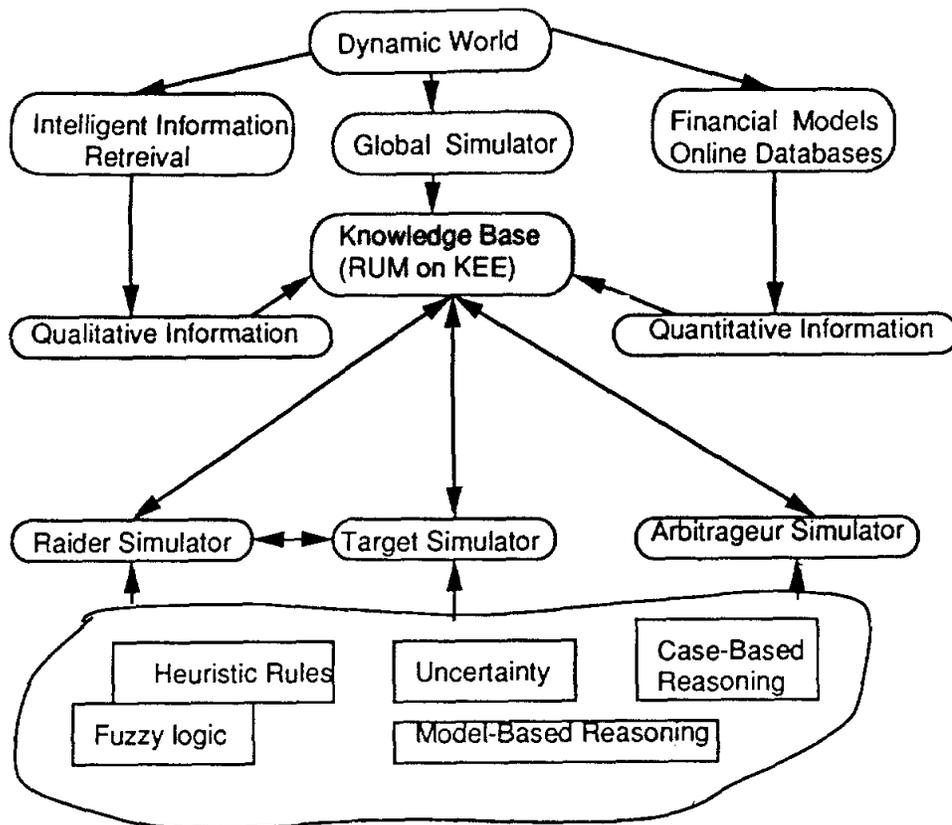

Figure 4: MARS Software Architecture

4.2.1 Nature of Facts & Rules

Both facts and rules in RUM can represent uncertainty. Facts are qualified by a degree of *confirmation* and a degree of *refutation*. For a fact A , the lower bound of the confirmation and the lower bound of the refutation are denoted by $L(A)$ and $L(\neg A)$ respectively. As in the case of Dempster's [Dem67] lower and upper probability bounds, the following identity holds: $L(\neg A) = 1 - U(A)$, where $U(A)$ denotes the upper bound of the uncertainty in A and is interpreted as the amount of failure to refute A . Note that $L(A) + L(\neg A)$ need not necessarily be equal to 1, as there may be some ignorance about A which is given by $(1 - L(A) - L(\neg A))$. The degree of confirmation and refutation for the proposition A can be written as the interval $[L(A), U(A)]$. This can be graphically represented as shown in Figure 6. In Figure 5, the uncertainty in the values of the various attributes (in the displayed windows) are depicted by such a graphical notation.

RUM provides a natural representation for plausible rules. Rules are discounted by *sufficiency* (S), indicating the strength with which the antecedent implies the consequent and *necessity* (N), indicating the degree to which a failed antecedent implies a negated consequent. Note that conventional strict implication rules are special cases of plausible rules with $S = 1$ and $N = 0$. Each rule has an associated *context* which represents the set of preconditions determining the rule's applicability to a given situation. This mechanism provides an efficient screening of the knowledge base by focussing the inference process on

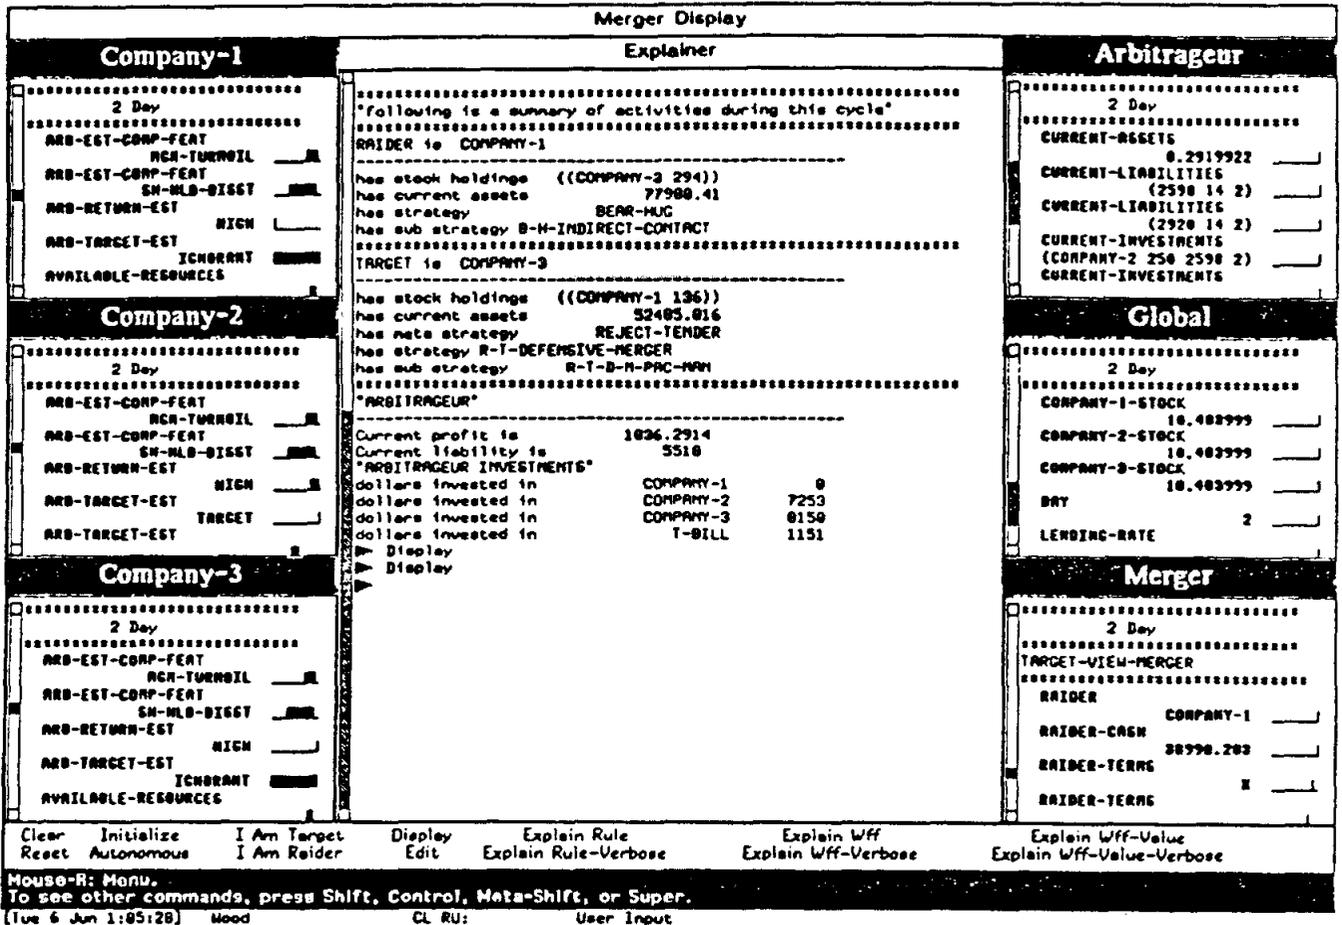

Figure 5: MARS User Interface

small rule subsets.

The general structure of a RUM rule is as follows:

```
(Rule-name Knowledge-Base-Name
Premise-List
Consequence-List
Premise-Slots
Context-List ;Optional
Sufficiency-Necessity-Pair ;Optional
T-Norm-Operator ;Optional
Context-Threshold ;Optional
Context-Flag ;Optional
Rule-Daemon) ;Optional
```

As shown, a rule consists of certain mandatory parts such as a *rule-name*, a *knowledge-base-name* (to which the rule belongs) and lists of premises, consequences and slots (of the

Figure 6: Graphical Representation of Uncertainty in Facts

frames or KEE units) used in the premise list. Other components of a rule are optional and default to certain values when not specified. These various components are briefly described below. A knowledge base can also contain rule templates, which when *instantiated* yield rules. For illustration purposes, we reproduce below a slightly edited rule template for the raider from MARS (from the knowledge base *company-kb*):

```
(add-template 'rd-target-mgm-friendly 'company-kb ;;line 1
 '(is-value? ?target 'raider-est-company-features :friendly-mgm) ;;line 2
 '(('bear-hug 'raider-desires-strategy :yes-desire-strategy));;line 3
 '((strategies-not-applied '(bear-hug) current-day));;line 4
 '*very-high-chance* *high-chance*);;line 5
 t3 ;; line 6
 '(b-h-selection) ;;line 7
 900) ;;line 8
```

This rule template called *rd-target-mgm-friendly* from the knowledge base *company-kb*, when instantiated for a given world state (i.e., a given raider and target) produces a rule in MARS. The (simplified) rule states that if the raider estimates that the target management is friendly (*premise - line 2*), then there is a very high chance (*sufficiency - line 5*) that he desires the bear-hug attack strategy (*conclusion - line 3*). Otherwise, there is a high chance (*necessity - line 5*) that he will not desire such a strategy. This rule is to be activated only if the bear-hug strategy has not been already applied (*context - line 4*). This context must be confirmed to a degree higher than 900/1000 (*threshold - line 8*) for it to be valid. Line 6 give the T-Norm operator used to aggregate the uncertainty in the rule and line 7 gives the name of the rule-class of which this particular rule is a member. A more detailed description of the meaning and implications of lines 5 and 6 is given below. Line 7 gives the name of the *rule-class* (see section 4.2.3) in the *company-kb* knowledge base to which this rule belongs. Fuzzy logic [Zad65] can be used in the rules to specify values in the above rule. For example the sufficiency and necessity measures (**very-high-chance** & **high-chance** - line 5) are fuzzy sets, with trapezoidal distribution functions. The use of fuzzy logic enables a much richer representation of imprecision in rule premises, conclusions and contexts.

4.2.2 Inference in Rule Graph

RUM provides an uncertainty calculus based on a set of five Triangular norms (T-norms) [Bon87b] for inference in the rule graph. T-norms and T-conorms are two-place functions from $[0,1] \times [0,1]$ to $[0,1]$ that are monotonic, commutative and associative. They are the most general families of binary functions which satisfy the requirements of the conjunction and disjunction operators respectively. Their corresponding boundary conditions satisfy the truth tables of the logical AND and OR operators. Five uncertainty calculi based on the following five T-norms are used in RUM:

$$\begin{aligned}
 T_1(a, b) &= \max(0, a + b - 1) \\
 T_{1.5}(a, b) &= (a^{0.5} + b^{0.5} - 1)^2 && \text{if } (a^{0.5} + b^{0.5}) \geq 1 \\
 &= 0 && \text{otherwise} \\
 T_2(a, b) &= ab \\
 T_{2.5}(a, b) &= (a^{-1} + b^{-1} - 1)^{-1} \\
 T_3(a, b) &= \min(a, b)
 \end{aligned}$$

Their corresponding DeMorgan dual T-conorms, denoted by $S_i(a, b)$, are defined as

$$S_i(a, b) = 1 - T_i(1 - a, 1 - b)$$

These five calculi provide the user with an ability to choose the desired uncertainty calculus starting from the most conservative (T_1) to the most liberal (T_3). T_1 (T_3) is the most conservative (liberal) T-norm in the sense that for the same input certainty ranges of facts and rule sufficiency and necessity measures, T_1 (T_3) will yield the minimum (maximum) degree of confirmation of the conclusion. For each calculus (represented by the above five T-norms), the following four operations have been defined in RUM:

Antecedent Evaluation. To determine the aggregated certainty range $[b, B]$ of the n clauses in the antecedent of a rule, when the certainty range of the i th clause is given by $[b_i, B_i]$:

$$[b, B] = [T_i(b_1, b_2, \dots, b_n), T_i(B_1, B_2, \dots, B_n)]$$

Conclusion Detachment: Modus Ponens. To determine the certainty range, $[c, C]$ of the conclusion of a rule, given the aggregated certainty range, $[b, B]$ of the rule premise and the rule sufficiency, s and rule necessity, n :

$$[c, C] = [T_i(s, b), 1 - (T_i(n, (1 - B)))]$$

Conclusion Aggregation. To determine the consolidated certainty range $[d, D]$, of a conclusion when it is supported by m ($m > 1$) paths in the rule deduction graph, i.e., by m rule instances, each with the same conclusion aggregation T-norm operator. If $[c_i, C_i]$ represents the certainty range of the same conclusion inferred by the i th proof path (rule instance), then

$$[d, D] = [S_i(c_1, c_2, \dots, c_m), 1 - S_i(C_1, C_2, \dots, C_m)]$$

Source Consensus. To determine the certainty range, $[L_{tot}(A), U_{tot}(A)]$ of the same evidence, A , obtained by fusing the certainty ranges, $[L_i(A), U_i(A)]$, of the i th information source out of a total of n different possible information sources:

$$[L_{tot}(A), U_{tot}(A)] = [Max_{i=1, \dots, n} L_i(A), Min_{i=1, \dots, n} U_i(A)]$$

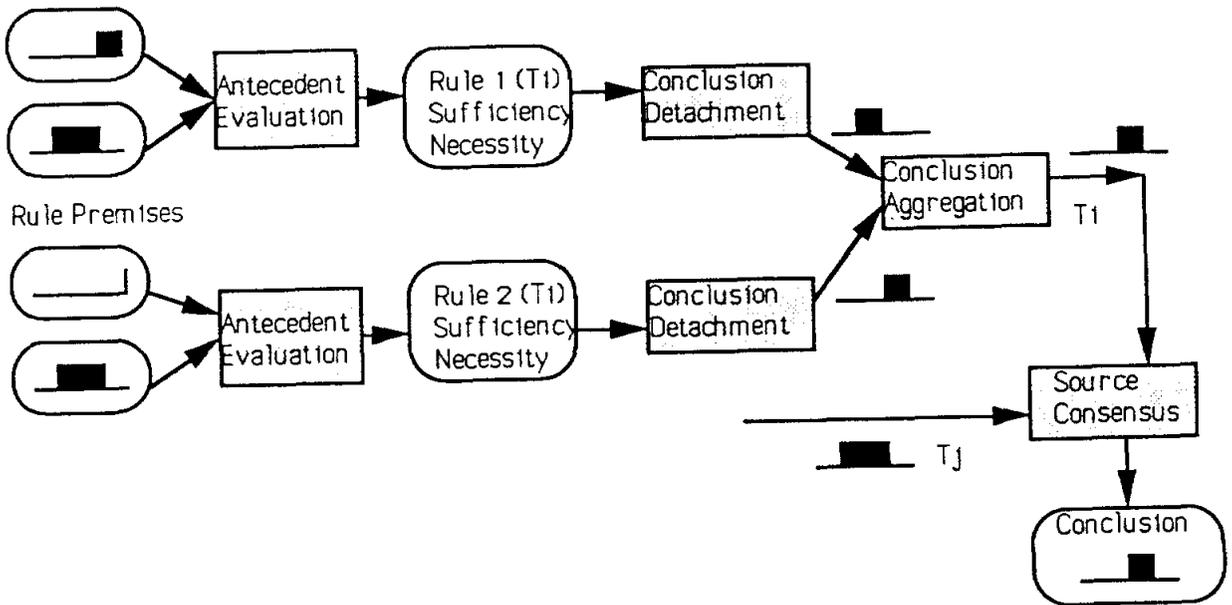

Figure 7: Inference Using Uncertainty in Rule Graph

Line 6 in the sample rule-template described earlier specifies the T-norm (T_i) operator selected to propagate uncertainty in the rule using the operations defined above. The use of these operations for inference in a simple rule graph is shown diagrammatically in Figure 7. The certainty ranges at various stages are depicted graphically. Note that the *Conclusion Aggregation* operation aggregates proof paths (rules) using the same T-Norm operator (T_i) while the *Source Consensus* operation aggregates proof paths using different T-norm (T_i and T_j) operators.

The theory of RUM is anchored on the semantics of many-valued logics [Bon87b]. Unlike other probabilistic systems, RUM's reasoning mechanism is possibilistic. References

[Bon87b], [BGD87] describe a comparison of RUM with other reasoning with uncertainty systems, such as Modified Bayesian [DHN76], Certainty Factors [SB75], [Hec86], Dempster-Shafer [Dem67], [Sha76], and Fuzzy logic [Zad65].

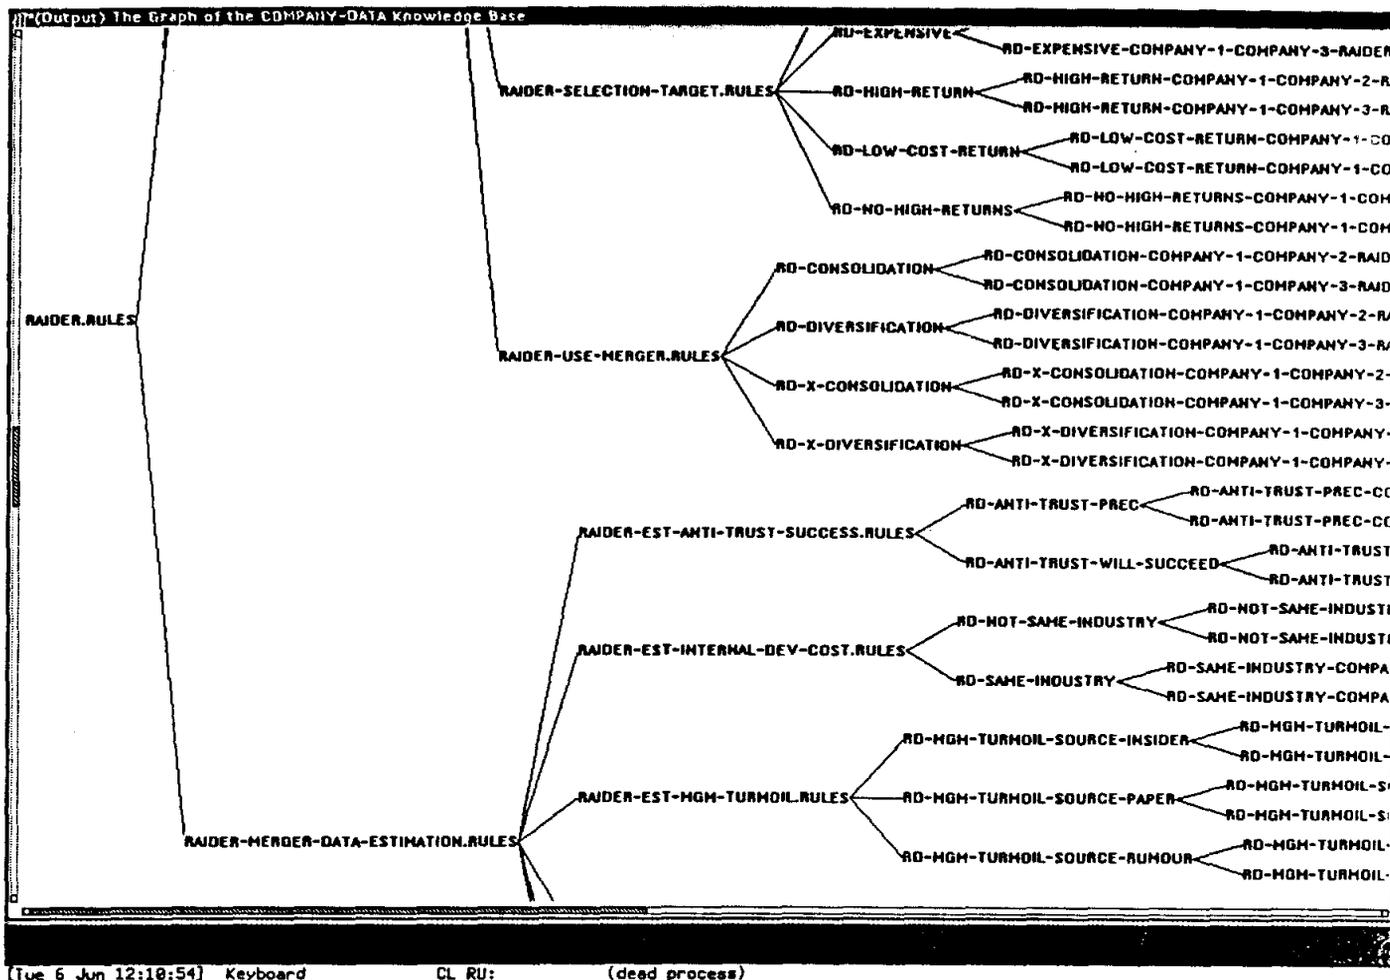

Figure 8: Partial Structure of Knowledge Base of MARS

4.2.3 Structure of Knowledge Base

The knowledge base of MARS contains approximately 550 rule-templates. Though not a very large number, it is sufficiently large to warrant structuring the knowledge base due to reasons explained in section 1.2. Related rules are clustered into subsets called *rule-classes* and these rule classes are organized into an abstraction hierarchy with specialization as one traverses down the hierarchy. Figure 8 depicts a partial abstraction hierarchy of rule classes from the MARS knowledge base for the selection of raider strategies. Note that the rule class titled *RAIDER-EST-ANTI-TRUST-SUCCESS-RULES* contains rules used by the raider to determine the possibility that an anti-trust move will succeed. The rules in this rule class are

further divided into two categories - rules related to the effect of prior cases (under *RD-ANTI-TRUST-PREC*) and rules related to other issues governing the success of the anti trust move (under *RD-ANTI-TRUST-WILL-SUCCEED*). This common representation of rules related to both prior cases and domain specific issues facilitates the seamless integration of RBR and CBR in MARS. The next few sections provide more details on this integration. The contexts of the rules in the rule-class collectively help define the conditions under which that particular rule-class is activated. Thus during inference, it is possible to focus and selectively search the rule graph so as to reach the desired solution as efficiently as possible. The expressiveness of RUM is enhanced by another function: *belief revision*, which is essential to the dynamic aspect of the domain of M&A. The belief revision mechanism detects changes in the input, keeps track of the dependency of the intermediate and final conclusions on these inputs, and maintains the validity of these inferences. For any conclusion made by a rule, the mechanism monitors the changes in the certainty measures that constitute the conclusion's support.

4.3 CBR in MARS

We will now turn our attention to the CBR component in MARS. We have outlined earlier (see section 1.2.2) the important issues within CBR. We explain below how each of these issues has been addressed in MARS.

Representation Given our intention to integrate RBR and CBR within the common architecture of rules, we decided to represent individual cases in the MARS case library as RUM rule-templates. The general structure of a rule template has been described in section 4.2.1. To see how cases are represented as rule templates, let us refer to section 3.3: the part of the Mobil-Marathon case described there is represented as the following (edited) rule template (expressed in psuedo English & Lisp):

(CASE 1)

```
IF (similar-industry ?raider ?target) AND (Ti)
    (large-merged-national-market
      ?raider ?target) AND (Ti)
    (significant-local-dominance ?raider ?target)
THEN 0.9 (sufficiency)
    (anti-trust-success ?raider ?target)
```

where (*T_i*) is the T-norm operator chosen for the conjunction of the rule premises. This rule template expresses the following: the facts that Mobil and Marathon operated in a similar industry sector and that the combined entity (if Mobil succeeded in taking over Marathon) would have a large national market share and significant local dominance were very important (to the degree 0.9) in determining the success of the anti trust move. Each premise (*similar-industry*, *large-merged-national-market* and *significant-local-dominance*) is an *abstract feature* and is implemented as a call to a procedure which returns an interval valued certainty measure (see sections 4.2.1 & 4.2.2) when the variables *?raider* and *?target* have been instantiated to a particular raider and target. This interval value reflects the degree

of match of the case with the probe - details are provided in later sections. The sufficiency measure, 0.9 , gives the degree to which the conjunction of the three premises is relevant for determining the success of the anti-trust suit in this case. (The necessity measure has been omitted for clarity). It should be noted that Mobil and Marathon have been replaced by the role variables $?raider$ and $?target$ respectively. The uncertainty mechanism supported by RUM rules is being used in this representation for two purposes: first, to represent the relative importance of the premises for the conclusion (by the choice of T_i - see section 4.2.2), and second, to represent the relevance of the premises to the conclusion (via the *sufficiency* and *necessity* measures).

The above rule template gives an *interpreted* description of a particular aspect of the Mobil-Marathon case, i.e., it states explicitly what the reasons (and their relative degrees of importance) were for the success of the anti-trust move in the Mobil-Marathon case rather than merely stating that the anti-trust move succeeded. It is of course important to consider means to obtain the interpreted rule templates from available data. This is possible in the domain under consideration. Consider the ruling of Judge Manos in the Mobil-Marathon case which outlined detailed reasons for the judgement. The above rule template is merely a translation of Judge Manos' ruling. An intelligent information retrieval system should be able to analyze such natural language data and extract the reasons (interpretations) for events and actions. SCISOR [JR90] is an intelligent natural language system which can perform this function. Reference [BD90] outlines this integration of SCISOR and MARS. In the absence of such recorded descriptions of events/actions and their interpretations, some inductive learning programs will have to be used to obtain the interpreted rule templates. Such an inductive learning capability is lacking in MARS.

Our choice of rule templates as the stored representation of cases in the case library departs from conventional representation (frames and MOPS [RS89a]) of cases (section 1.2). We feel that this departure is justified as it is possible to achieve a seamless integration of CBR and RBR in MARS using such a representation. This would have been very difficult had we used different representations for cases and rules. Also, as RUM rules are richer data structures (with *contexts*, *thresholds*, *sufficiency* & *necessity measures* and *fuzzy values*) than simple categorical IF..THEN.. rules, it is possible to adequately represent many features of cases required for CBR. One disadvantage of using rule templates to represent cases is that they cannot be used if some of the rule premise (abstract feature) data is not available for the current problem (probe).

Structure of Case Library Any particular case, such as the Mobil-Marathon case described earlier, has many other interesting aspects (besides the anti-trust suit) and there are many other cases in the case library which deal with the topic of anti-trust moves (e.g., cases related to *Brown Shoe* and *Kinney Co.* and *Pabst Brewing Company*). In the MARS case library, a *hierarchical, functional* structure is imposed on the cases in the case library. Figure 9 illustrates the partial structure of the case library. (Note that the case library is not shown in figure 8).

As shown, the case library has at the top level two branches, one containing cases pertaining to *defensive* strategies and the other related to *attack* strategies. Within the defensive strategies category, we have sub-categories for cases related to different types of defensive strategies (e.g., *pac-man*, *greenmail* and *anti-trust*). Going further down the sub-category

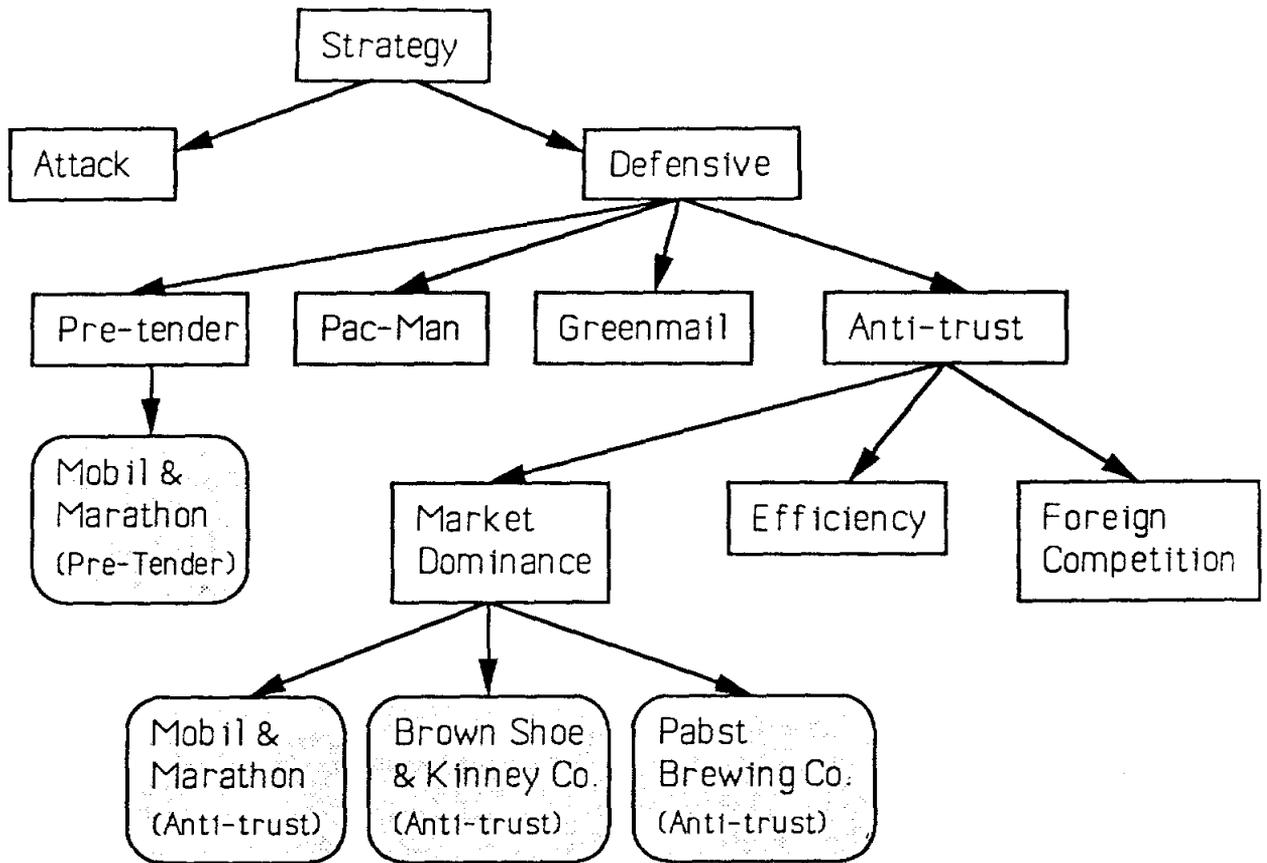

Figure 9: Partial Structure of Case Library in MARS

for anti-trust defensive strategy cases, we have sub-sub-categories for cases related to *market dominance*, *efficiency* and *foreign competition*. The example rule template, CASE 1, (described above) is contained in the market dominance category. Note that all case descriptions relevant for the *market-dominance* aspect of the *anti-trust* move are grouped together. Thus the templates for Pabst Brewing Company and Brown Shoe-Kinney all appear together with the template for Mobil-Marathon. Note also that all aspects of a particular case are not stored together. Thus templates pertaining to different aspects of the Mobil-Marathon case are distributed appropriately in different parts of the case library hierarchy. For example, the rule templates expressing the *pre-tender* defensive strategies related to the Mobil-Marathon case are stored under the sub-category *pre-tender* defensive strategies as shown in Figure 9. For simplicity, the different types of pre-tender defensive strategies (e.g., *poison pills*, *shark repellants* and *crown jewel lock ups*) are not shown in Figure 9.

As mentioned earlier, flat memory structures and discrimination networks are popular methods for structuring the case library in the literature. Flat structures are expensive to search sequentially and thus discrimination networks are more widely used. The hierarchical, functional structure of the MARS case library, while similar in many aspects to a discrimination network, is different in emphasizing the functional break-up of a case into different parts of the case library and grouping of similar parts of many different cases into the same part of the case library. While such an approach has some disadvantages (as discussed in

section 5.2), it forces a cleaner structure on the case library and yields simpler retrieval mechanisms.

Need for CBR. It is important to recognize two points. First, CBR is important only for certain problems and goals. It is not useful to always consider CBR. For example, in the domain of M&A, CBR is useful primarily for structuring the legal and tax aspects of the deal. For some other aspects, such as use of statistical financial models, it makes little sense to include CBR. Second, CBR is, in general, only one approach (proof path) to the solution of a goal/problem. There are (usually) other approaches (or proof paths) to the same goal/problem and it is important to consider the contributions of all paths, proportional to their relative importance. These aspects are significant, as most research in CBR has considered it in isolation till now.

In MARS, the inference process can be considered as the traversal of paths in a rule graph. Premises, qualified by certainty intervals, combine (using RUM's uncertainty calculi) to generate conclusions (also qualified by certainty intervals) which either again act as premises for other rules or generate final conclusions. The decision whether to activate CBR or not is left to the designer of the system. Whenever the expert (or system designer) feels that CBR is important for deciding about a particular conclusion, a rule to this effect is added in the knowledge base. For example, consider a hypothetical M&A deal, M1, being analyzed by MARS. As precedents are important for the evaluation of the possibility of success of an anti-trust suit in M1, a rule to this effect is added (under the rule class *RD-ANTI-TRUST-PREC* - see figure 8):

(RULE 1)

```
IF similar anti-trust precedent exists
THEN 0.8 (sufficiency)
    anti-trust successful in M1
```

This rule (shown as rule 1 in Figure 10) states that *if there is a precedent of an anti-trust move succeeding in a similar situation (as in M1), then that might cause the anti-trust move succeeding in M1 to the degree 0.8*. Rule 1 shown above is, of course, a simplified English like representation of an actual rule and omits features like *context lists*, *thresholds* and the *necessity measure*. However, the presence of a prior precedent is not the only fact affecting the outcome of an anti-trust move in M1. There are, in general, other factors (e.g., the "political lobbying power of the target") that also either confirm/disconfirm the conclusion. A rule (shown as RULE-2 in figure 10) is therefore added (under the rule class *RD-ANTI-TRUST-WILL-SUCCEED* - see figure 8):

(RULE 2)

```
IF target has strong political lobby
THEN it is likely (sufficiency)
    anti-trust successful in M1
```

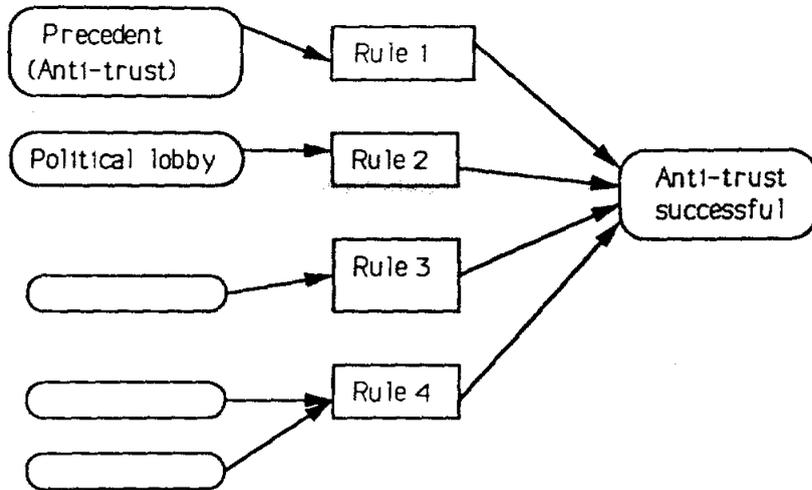

Figure 10: Example of a Simple Rule Graph

The above two rules represent two different proof paths, each contributing to the determination of the goal “*anti-trust successful in M1*” (see Figure 10) The *conclusion aggregation* and *source consensus* operations (see section 4.2.2 and Figure 7) determine the relative contributions of RULE-1 and RULE-2 to the final conclusion of “*anti-trust successful in M1*”.

Note that the uncertainty mechanism of RUM is being used to (a) represent the importance of a prior precedent for the current conclusion (RULE-1) and (b) aggregate the relative importance of different proof paths - of which CBR is but one possible proof path.

This emphasis on *explicitly recognizing the need for CBR* is novel to our research. As mentioned before, most prior research in CBR has ignored this issue, having considered CBR in isolation. The work by Rissland & Skalak [RS89b] has also studied the need for deciding when to use CBR. However their approach is very different as it requires a central scheduler to decide upon the invocation of CBR based on some heuristics. They do not consider the use of CBR and RBR as parallel proof paths. They use either CBR *or* RBR at any one time, depending upon which is feasible. This is in contrast to our approach in which both CBR and RBR are considered as two equal proof paths in parallel, and each makes a proportional contribution to the confirmation/disconfirmation of the conclusion.

Retrieval & Similarity Metrics Recall that a RUM rule template (section 4.2.1) has a context which keeps track of the environment in which that rule is activated. This context of rules is used to efficiently index into the hierarchical structure imposed on the case library. For example, if the context indicates that anti trust success is being evaluated, only relevant cases will be retrieved by following down the appropriate path in the case library hierarchy (see Figure 9).

In conventional CBR, the general approach is to retrieve *one* prior case that is most *similar* to and *relevant* for the current goal/problem. The approach taken in MARS departs from this in that it retrieves *all relevant* cases and then proportionately weighs the relative contribution of each relevant case. For an example, consider Figures 9 and 10. In Figure 9,

there are three *case rule templates* under the *anti-trust* branch. When the inference engine of MARS encounters RULE-1 (in Figure 10), it goes into the case library hierarchy (Figure 9) and retrieves all relevant cases (here the three *case rule templates*: *Mobil-Marathon*, *Brown-Shoe-Kinney & Pabst-Brewing*).

The matching process is operationalized by instantiating the case rule templates in the case library to the situation of the current world, M1. This process converts the case rule templates to rules which can be used in the reasoning process of M1 and at the same time determines the degree of relevance of the previous cases to M1. Thus if CASE-1 (case rule template) were instantiated to M1 world conditions, the variables *?raider* and *?target* would be instantiated to the raider and target respectively in M1, and each of the three premises will be evaluated to yield certainty ranges which give the degree to which the premises of the case are true in the current M1 world. If they are not relevant (true), a very low confirmation for the premises will be obtained and vice versa. Using the uncertainty calculi of RUM (section 4.2.2), CASE-1 will yield a conclusion with a certainty range which is the degree to which that case is similar to and relevant for M1. As there will be many cases for the same conclusion (e.g., successful anti-trust cases) in the case library, an aggregated value of the relevance of all the previous cases can be obtained using the *conclusion aggregation* and *source consensus* operations of RUM's uncertainty calculi.

The interval valued certainty ranges obtained when the premises of case rule templates are instantiated to the current world conditions are the same as the intervals, $[N(p | d), P(p | d)]$, representing the lower and upper bounds on the degree of match between the pattern (cases) and data (probes). Here the *necessity measure* $N(p | d)$ represents the degree of semantic entailment of a pattern descriptor p given a datum d and the *possibility measure* $P(p | d)$ represents the degree of intersection between the same pattern and datum.

Adaptation Once the relevant cases have been retrieved from the case library, the *adaptation* phase of CBR in MARS is performed by the process of *reinstatiation* of the case-rule-templates to the current world situation and the application of the uncertainty propagation mechanism of RUM (section 4.2.2).

The process of *reinstatiation* is closely intertwined with the *matching* process as described above in the section on *Retrieval & Similarity Metrics*. When CASE 1 (case rule template) is reinstatiated to the current situation (M1), the certainty measures associated with the evaluation of each of the premises indicates the degree to which those premises are valid in the current situation, or in other words, it represents the result of the *adaptation* of the premises to the current problem. The aggregated uncertainty of the premises is propagated forward using the uncertainty calculus supported by RUM to contribute to the confirmation/disconfirmation of the conclusion (node labelled *anti-trust success* in Figure 11). However the process of adaptation is not complete at this stage as there are other relevant cases which also have to be considered. The other case rule templates (*Brown-Shoe-Kinney* and *Pabst-Brewing* in Figure 9) will also yield on reinstatiation similar contributions to the confirmation/disconfirmation of the conclusion (node labelled *precedent (anti-trust)* in Figure 11). Using the *conclusion aggregation* and *source consensus* operations (section 4.2.2), the proportional contributions of all three case rule templates can be combined to yield an aggregated measure of confirmation/disconfirmation for the conclusion "*precedent (anti trust)*". This process has been illustrated in Figure 11.

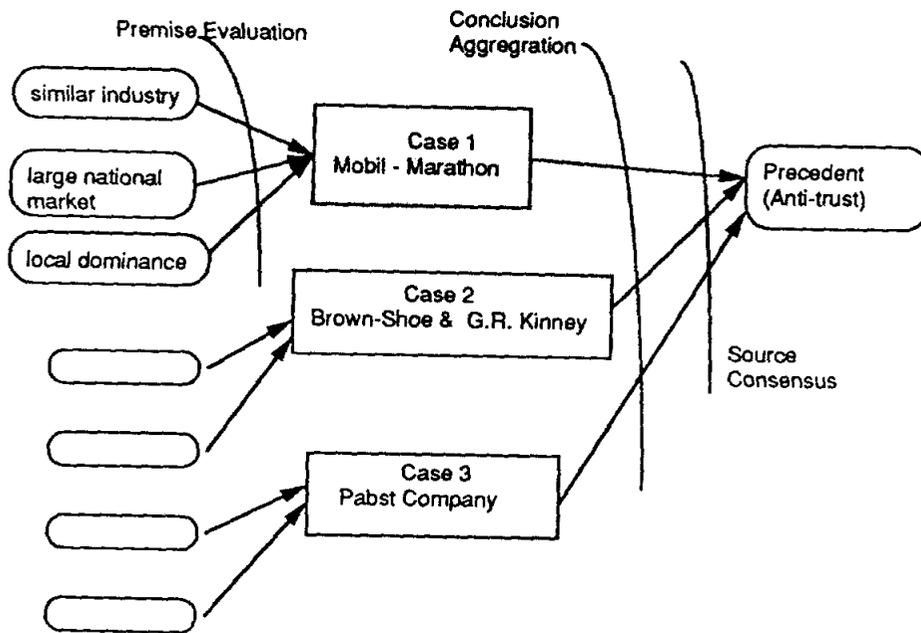

Figure 11: Expansion of Case Library During Case Adaptation

The next stage in the adaptation phase is to notice that the nodes labelled *prior precedent (anti trust success)* are the same in Figures 10 and 11. Once the aggregated contribution of all relevant cases has been obtained (by the process described above), it gives the degree of confirmation/disconfirmation of the premise of RULE-1 (Figure 10). The net contribution of CBR to the current conclusion - "anti trust successful in M1" (node labelled *anti-trust successful* in Figure 10) can then be obtained by applying the usual T-norm calculus to RULE-1.

The adaptation procedure described above is a variation of *parametric adaptation* when the goal variable (conclusion - node labelled *Precedent (Anti-trust)* in Figure 11) has only one value (anti-trust success in Figure 11). In general, the goal variable can have multiple values. For example, the goal variable can be *value of tender offer*, which can take a number of different values in different cases as shown in Figure 12. Each of these values is qualified by a lower and upper bound on its certainty (the thick portions of the lines gives the bounds - using the same graphical notation as in Figure 6) and together they define a distribution. The value given by case based reasoning has to be obtained by interpolation on such a distribution. The interpolation mechanism chosen is domain dependent.

The adaptation phase of CBR in RUM is also different from that common in the literature. Though *derivational* in approach, it relies extensively on the the uncertainty calculus supported by RUM. Indeed, it is the rich T-Norm calculus supported by RUM that makes this possible. The above process of adaptation has its limitations in that it does not allow any structural changes (in the case rule templates), but more important, it allows the adaptation phase to be integrated into the normal inference cycle of RBR in MARS. This was a crucial goal for our research. It also allows the simultaneous consideration of many different

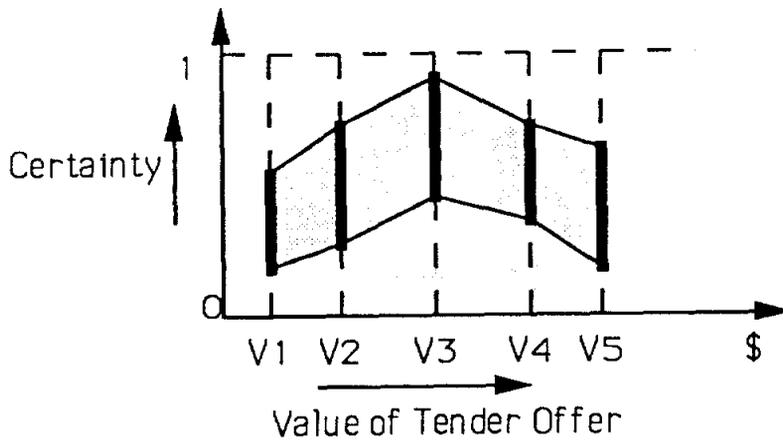

Figure 12: Interpolation With Multiple Values

relevant cases. By suitably changing the T-norm operators, it is possible to easily adjust the relative contributions of various cases in the CBR process. The lack of an ability to make structural changes in the case rule templates can be overcome partly by introducing additional proof paths (e.g., rules 2 and 3 in Figure 10) and proportionately weighing their relative contributions.

Integration Though most prior research in CBR has considered it in isolation, an important goal of our research was to try and integrate it seamlessly into RBR. The motivations for this were explained in section 1 (also see Figure 3).

The above sub-sections taken together, have outlined the details of the integration of RBR and CBR in MARS. The inference engine of RBR in MARS is the dominant inference cycle and under normal circumstances goes about its task of searching through the rule graph of the MARS knowledge base. When it comes across a rule premise involving CBR (see RULE-1), it begins evaluating the premise much as it does for any other normal (not involving CBR) rule. However for evaluating the premise of a rule using CBR, it has to go and retrieve the relevant cases from the case library, which results in the expansion and search of an additional rule graph (involving the case rule templates - see Figure 11). Once the rule graph involving the case rule templates (Figure 11) has been evaluated, it returns with the confirmation/disconfirmation of the premise of the rule involving CBR (RULE-1) and carries on with the normal inference propagation mechanisms. Note that the only difference in the evaluation of the premise of a rule involving CBR occurs in the fact that while most premises of normal rules require simple matches or procedure calls, the premises of rules involving CBR require the expansion and searching of an additional rule graph (corresponding to the case rule templates).

Thus to summarize the process briefly:

- Cases are stored as rule templates (CASE 1).
- If CBR is important, a rule to this effect (RULE 1) is added.
- Case rule templates are instantiated automatically while evaluating the premise of rules like (RULE 1). Rule contexts are used for indexing into the hierarchical structure of the case library.

- Adaptation of cases is performed by the process of instantiating the case rule templates and using the T-Norm calculus to propagate the inference forward.

Finally, we would like to emphasize two points. First, note the seamless and compact integration of RBR and CBR. No changes need to be made in the inference engine of RBR in MARS (which remains the same whether CBR is used or not) for accommodating CBR. Second, the uncertainty calculus supported by RUM plays a major role in the entire process, right from representation upto adaptation and integration.

5 Conclusion

5.1 Comparison with Related Research

As mentioned earlier, there has been very little research in combining RBR and CBR. The only work in this area that the authors are aware of is that of Rissland and Skalak [RS89b]. Their approach however, is very different. While working in the legal domain of *statutory interpretation*, they have built a system called CABARET, whose architecture consists of two co-equal reasoners, one a RBR and the other a CBR, with a separate agenda based controller. The central controller contains heuristics to direct and interleave the two modes of reasoning and to post and prioritize tasks for each reasoner. Though this effort should be credited for being the first in addressing such an important issue, we have decided to take a different approach to integrating RBR and CBR. First, we have chosen rule-templates (as opposed to frames in CARARET) as the representation schema for cases. This has allowed us to use a similar data representation for both RBR and CBR and obviated the need to "patch together" frames and rules. Second, we have required the user or system designer to explicitly recognize the need for CBR for a particular conclusion. This approach requires some participation from the system designer, but does not require a central scheduler or controller. We feel that it may be difficult to always choose the right heuristics for the controller and to design it to perform correctly and adequately in different, complex domains. Third, we do not activate only one reasoning methodology (RBR or CBR) at a time (as in CABARET), but rather consider them in parallel as two equal proof paths, each making a proportionate contribution to the final conclusion/goal. Fourth, the case library and the retrieval mechanisms in MARS are structured so as to consider the relative contributions of all relevant cases to the conclusion. Finally, our approach to integrating RBR and CBR provides a treatment of uncertainty and approximate matching between input and cases, which is not available in CABARET.

5.2 Contributions and Limitations

We feel that the primary contribution of this paper has been to illustrate the compact and seamless integration of RBR and CBR as implemented in MARS. Both RBR and CBR are very important reasoning methodologies and it is surprising that there has been such little prior work in integrating the two. We hope that this paper represents a major effort in that direction. Both RBR and CBR are required for solving complex real world problems. By choosing RBR as the base architecture for integration, we have illustrated a method for

adding more power to rule based systems, i.e., expanding their inference capabilities. Our architecture treats the contributions of CBR and RBR simultaneously and proportionately (according to their relative importance) as separate proof paths to a conclusion. This does not require the use of any special heuristics or agendas. As shown, no changes have to be made to the inference engine of RBR to accommodate CBR. Furthermore, this seamless integration is anchored on common possibilistic semantics for both CBR and RBR. The methodology presented in this paper is general and also applies to RBR without uncertainty (where rules and facts are special cases of RUM rules and facts) and to both problem solving CBR and precedent based CBR (as long as the base architecture is rule based).

We will conclude our discussion by noting some of the limitations of the methodology described in this paper and by proposing future efforts aimed at strengthening this approach. The case library consists of interpreted rule templates (cases) which are conditioned on a specific goal (*saliency*). The process of interpretation of data to obtain such rule templates, though possible, is non-trivial. The important goals (to be included in the case library) and the salient features for each goal (expressed in the rule templates representing cases) have to be explicitly engineered into the system. Also, the case library at present has to be necessarily incomplete (as it is not possible to represent all possible relevant features/reasons for all possible events/actions). The system designer has to decide the importance of various goals, the relevancy of different features for the goals and construct the case library. Any automation of this process would be a significant improvement. Some algorithms for automating the determination of the relevancy of attributes for a goal are given in [Dutng] and we are looking into the incorporation of those techniques into MARS. The hierarchical, functional structure imposed on the case library while making retrieval easy and manageable, does impose restrictions on frequent changes and updates in the structure of the case library. As implemented, we have chosen to retrieve all relevant cases; however, this may not be such a good idea if the number of cases increases to a very large number. Under such conditions, we will have to consider means to limit the number of cases retrieved, by imposing either simple measures like thresholds or more complex measures like dynamic relevancy metrics. All these issues will be the focus of our research goals for the near future.
